Lecture XXVI: Behind pymc

Behind PyMC

The probabilistic programming approach of PyMC is built on two “technologies”:

- ① A library that mixes numerical and symbolic computations (Theano, Aesara, currently a new implementation called PyTensor)
- ② Markov Chain Monte-Carlo (MCMC) algorithms to estimate posterior densities

PyQB

PyTensor
Monte-Carlo

PyTensor

It bounds numerical computations to its symbolic structure (“graph”)

```
import aesara as at

a = at.tensor.dscalar()
b = at.tensor.dscalar()

c = a + b**2

f = at.function([a,b], c)

assert f(1.5, 2) == 5.5
```

Symbolic manipulations

Variables can be used to compute values, but also symbolic manipulations.

```
d = at.tensor.grad(c, b)

f_prime = at.function([a, b], d)

assert f_prime(1.5, 2) == 4.

Note you still need to give an a because the symbolic structure
needs it.
```

Metropolis

The easiest MCMC approach is the so-called Metropolis algorithm (in fact appeared as Metropolis, N., **Rosenbluth, A., Rosenbluth, M.**, Teller, A., and Teller, E., 1953)

```
steps = 100000
positions = np.zeros(steps)
populations = [1,2,3,4,5,6,7,8,9,10]
current = 3

for i in range(steps):
    positions[i] = current
    proposal = (current + np.random.choice([-1,1])) %
        len(populations)
    prob_move = populations[proposal] /
        populations[current]
    if np.random.uniform(0, 1) < prob_move:
        current = proposal
```

164

Markov Chain Monte-Carlo

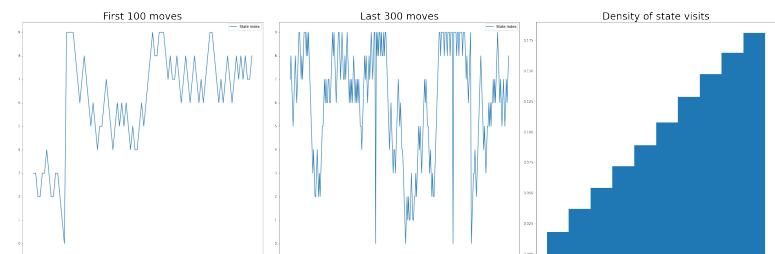

PyQB
Monga
PyTensor
Monte-Carlo

It's way of estimating (relative) populations of "contiguous" states.

- It needs the capacity of evaluate the population/magnitude of any two close states (but a global knowledge of all the states *at the same time*)
- It's useful to estimate *posterior distribution without explicitly computing P(D)*: $P(M|D) = \frac{P(D|M) \cdot P(M)}{P(D)}$

163

Convergence

Eventual convergence is guaranteed, but it can be painful slow (and you don't know if you are there...). Many algorithms try to improve: Gibbs, Hamiltonian-MC, NUTS...

Putting them together

```
import pymc as pm

linear_regression = pm.Model()

with linear_regression:
    # PyTensor variables
    sigma = pm.Uniform('sigma_h', 0, 50)
    alpha = pm.Normal('alpha', 178, 20)
    beta = pm.Normal('beta', 0, 10)
    mu = alpha + beta*(adult_males['weight'] -
        ↪ adult_males['weight'].mean())
    # Observed!
    h = pm.Normal('height', mu, sigma,
        ↪ observed=adult_males['height'])

trace = pm.sample() # MCMC sampling
```
